

NEUROFIBROMATOSIS TYPE 1 AND OPTIC PATHWAY GLIOMA

SUMMARY

Purpose: Evaluate the effectiveness of treatment of patients with optic pathway glioma.

Materials and Methods: Comparison of literature research on neurofibromatosis and optic pathway glioma with a cohort of pediatric patients treated at the Children's Ophthalmology Clinic of the University Hospital in Brno from January 2013 until June 2018.

Discussion: The main challenge of this and other retrospective studies is variable intervals between ophthalmologic examinations. In some pediatric patients it is also difficult to objectively assess visual functions. The main risk factors are age at the time of treatment and tumor localization. Tumor progression itself does not always correlate with worse visual acuity outcomes, and it remains to be evaluated whether some patients would be better off without treatment. As of now, there are no clinical biomarkers able to predict impending visual acuity loss.

Conclusion: The cohort outcome agrees with literature. Chemotherapy remains a treatment of choice and its most likely outcome is visual acuity stabilization. In order to properly evaluate the treatment's effectiveness, better collaboration between medical specialists and regular standardized ophthalmology examinations are required.

Key words: neurofibromatosis, children, optic pathway glioma, chemotherapy, treatment

NEUROFIBROMATOSIS TYPE 1

With an incidence of 1/3000 live-born children, neurofibromatosis type 1 (NF1) is one of the most commonly occurring autosomal-dominant hereditary diseases in humans (30). Approximately half of the cases are hereditary, and the remaining 50% occur based on new mutations (26). New mutations usually appear in paternal chromosomes. One of the explanations is that the higher age of the fathers at the time of conception leads to a long-term methylation of the DNA of some sperm cells, triggering point mutations which have the consequence of an increased incidence of sporadic NF1. "The cause of development of the pathology is a mutation of a tumour-suppressor gene of NF1 (17q11.2) and subsequent malfunction of formation of the cytoplasmic protein neurofibromin. In the case of NF1, this malfunction is linked with an incidence of multiple tumorous processes, which histologically correspond to hamartomas or benign tumours. Tumours of the central nervous system (CNS) are predominantly low-grade gliomas

(pilocytic astrocytoma, grade I), especially in the region of the visual pathway (33)."

CLINICAL PICTURE

Coffee stains (café-au-lait) – this skin symptom is almost always present. It is a multiple, light brown, smooth, sharply bordered pigmentation on the level of the skin. Stains are most often localised on the chest, but also on the limbs and face.

They originate through an accumulation of pigment melanoblasts on the basal layer of the epidermis, and a subsequent malfunction of the development of melanocytes (21). They occur in newborns, but their size and number may increase with age (19, 21, 30). For a definitive diagnosis of NF1, at least 6 stains, with a diameter larger than 5 mm in children and 15 mm in adults, must be present (30, 40). No relationship exists between the number of stains and the severity of NF1 (27). **Lisch nodules** are a useful diagnostic criterion of NF1. These are multiple hamartomas on the iris, usually found bilaterally.

They are found in a small percentage of children, but they appear in more than 90% of individuals aged over 6 years (23, 27). Initially, melanocytic hamartomas are light-coloured, but darken with age (19, 21, 30). **Freckling** – varying number of small rounded macules with pronounced pigmentation. They are located in the underarm and groin, and appear between the 3rd and 5th year of life.

A **neurofibroma** may appear anywhere in the peripheral nerve. If more than two appear, they represent one of the diagnostic criteria of NF1. Neurofibromas manifest themselves before the onset of or during puberty, and may also be found in persons without NF1 diagnosis. In the case of small lesions, skin neurofibromas can be removed with laser. In the case of larger lesions, priority is given to surgical removal, but here there is a risk of healing with a hypertrophic scar and recurrence of neurofibromas (33).

A **plexiform neurofibroma** (PN) may appear on all parts of the body where there are peripheral nerves. It is abundantly vascularised, not encapsulated, and does not metastasise. It

often manifests infiltrative behaviour (2). The transformation of a benign PN into a Malignant Peripheral Nerve Sheath Tumour (MPNST) represents an 8-13% lifelong risk (14). Symptoms of a PN's malignant character include change of consistency, and aggressive growth (2). Following a diagnosis of MPNST, patients already diagnosed with NF1 have a 5-year survival prognosis of 21%, while those without NF1 have a survival prognosis of 42%. MPNST is the most frequent cause of death in adults with a diagnosis of NF1 (14). PN occurs predominantly in orbito-palpebral form. The clinical symptoms may be expressed in newborns, but frequently manifest in the first years of life and progression is generally evident during puberty. Affliction is always unilateral and occurs more frequently in boys. The region of predilection is the outer half of the upper eyelid and the ceiling of the eye socket. Typical manifestations are deformation and hypertrophy of the upper eyelid with palpable nodules, protrusion and dislocation of the eyeball in a downward direction, enlargement of the eye socket, and bulging of the fossa temporalis due to long-term persistent expansion of the volume of soft tissues. Neurofibro-

ma is the main cause of enlargement of the eye socket, whose ceiling may show signs of severe skeletal dysplasia. In the case of a defect of the orbital ceiling, the meningoencephalocele bulges into the eye socket, transmitting brain pulsation to the contents of the orbit and giving rise to pulsating exophthalmos. The skin of the eyelid is pigmented, pliable (*cutis lata*), with angioectasias showing through. Affliction of the extraocular muscles and intraconal sensory and motor nerves may occur. On magnetic resonance imaging (MRI), T1 is hypointense and T2 hyperintense (2). In the case of neurofibromas, which are problematic in their localisation, painful even at rest, grow rapidly, and influence their surrounding area, a surgical procedure is most often applied. However, treatment of PN is problematic, the recurrence rate in children is as high as 75% (32). From a histological perspective, optic pathway glioma (OPG) is a spongioblastoma, astrocytoma, or oligodendrocytoma. The tumour originates through hyperplasia of the neuroglia in the trunk of the optics, penetrates through the pial sheath, and spreads in the intervaginal spaces, where it causes massive proliferation of mesothelial cells. This represents a characteristic property of this tumour. OPG is manifested macroscopically as a spindle-shaped swelling of the optics in the eye socket or in the cranial cavity, or has a dumbbell-shaped appearance if present in both cavities. The initial symptom is a malfunction of vision, which, however is generally not recognised early enough. The first reason for examination in children is strabismus ex anopsia, more frequently convergent than divergent, and progressing axial protrusion of the eye without malfunction of motility, edema, or reddening. It is possible to observe a relative afferent pupillary defect (RAPD) on an eye with exophthalmos. On images obtained from computed tomography (CT), there is a typical spindle-shaped thickening of the nerve throughout the entire course of the orbit, smoothly and sharply contoured. On X-ray images, it is expressed by a concentric extension of the canal beyond a diameter of 5.5 mm, without abrasion and destruction of the surrounding tissue. Extension of 6 mm or more, as well as a lateral difference of more than 20% or greater than 1 mm, is considered a pathological value of extension. The diagnostic picture of chiasmal glioma is a pear-shaped base noticeable in a lateral projection, caused by an extension of the ventral part of the sella turcica, resulting from pressure exerted by the glioma.

In the case of orbital gliomas, simple atrophy or edema of the optic nerve disc may be visible on the ocular fundus. Bilateral finding of congested papilla or combination of congestion and atrophy points to an affliction of the hypothalamus and the floor of the 3rd brain ventricle, with blockade of cerebrospinal fluid circulation and internal hydrocephalus.

Chiasmal gliomas are divided into two clinical types. An anterior optic chiasmal tumour has the same clinical picture, diagnosis, and prognosis as an optic glioma. A posterior hypothalamic chiasmal tumour represents a primary glioma of the hypothalamus and therefore has a different biological character. It is a malignant tumour, infiltrating the chiasma secondarily, and its rapid and aggressive growth leads to a fatal outcome. Functional symptoms of chiasmal glioma include progressive malfunction of vision, blind spots in the visual

Fig. 5. MR T2 TSE sectional trans. scan of optic glioma with slight protrusion of right eyeball. Source: Children's Radiology Clinic, Faculty of Medicine, Masaryk University and University Hospital Brno

field, and disorder of colour perception. An image of ocular fundus shows congested papillae, progressing to atrophy of the papillae. There is often present internal hydrocephalus with paralysis of the abducens nerve, with diencephalic symptomatology and disorder of growth (2, 21, 29, 30, 31). The best method for estimating the extent of an OPG is MRI with gadolinium (38). Other diagnostic methods are CT, diffuse tensor imaging, and diffuse tensor tractography. On MRI, optic gliomas are T1 hypointense or T1 isointense and T2 hyperintense (35). At present, glioma is most often treated by chemotherapy according to the SIOP protocol for low-grade tumours, using carboplatin and vincristine. More on therapy and its issues in the retrospective study. **Other clinical symptoms** – up to 85% of children with NF1 have FASI (Foci of Abnormal Signal Intensity) or UBO (Unidentified Bright Object); hypersignal lesions in T2 balanced images on MRI of the brain and spinal cord (18, 32). This probably concerns aberrant myelinisation with a vacuolar change of myelin located in the region of the basal ganglia, globus pallidus, in the thalamus, cerebellum, brain stem, and subcortical area predominantly in the temporal region. They are not saturated following an

Fig. 6. Photograph of fundus of OD: edema of papilla and atrophy of papilla in patient with optic glioma. Source: Children's Ophthalmology Clinic, Faculty of Medicine, Masaryk University and University Hospital Brno

application of a contrast substance and do not exert pressure on the surrounding structures, by which they differ from low-grade gliomas. FASIs are asymptomatic from a lesion neurological perspective but may be linked with cognitive malfunctions in NF1. In adulthood, they tend to diminish in size or disappear, and are rare in individuals over 30 years of age. A chance finding on MRI is intraspinal tumours, which manifest themselves more slowly than intracranial tumours. Non-tumorous manifestations of NF1 include small growth with abnormal values of growth hormone, macrocephaly and skeletal anomalies upon a background of congenital dysplasia of long bones, most frequently the tibia, manifested in newborn or breastfeeding age. Scoliosis also appears, which worsens with age. Systemic hypertension is most often renovascular, in which stenosis of the renal artery occurs on a background of fibromuscular dysplasia. These vascular changes may occur also elsewhere. A rare occurrence is a moya-moya syndrome, which is accompanied by the risk of ischemic stroke. It originates in connection with previous radiotherapy of tumours of the CNS (32). Mild mental retardation affects 29-35% of individuals with NF1 (13, 39). Specific developmental learning and behavioural disorders appear. Epilepsy occurs in up to 7% of children and is predominantly secondary upon expansive processes of the CNS (40, 18). An overview of the diagnostic criteria for NF1 is presented in table 1.

OPTIC PATHWAY GLIOMA

Optic pathway glioma (OPG) is the most common tumour of the optic pathway. It accounts for 3-5% of brain tumours in children (25, 35), 75% of optic tumours, and 10% of tumours of the eye socket (2). It belongs among low-grade gliomas (LGG), which are the most common brain tumours in children. The prognosis of survival for patients with LGG is 94% 10 years after diagnosis (20). Approximately half of all LGGs are asymptomatic. The first choice of treatment is generally chemotherapy, after which the tumour stabilises in 44% of cases. Radiotherapy leads to stabilisation in 62% of cases (20). However, these numbers are not related to visual acuity (VA) outcomes and quality of life. Boys are less susceptible to tumours than girls (12) and they also manifest longer tumour stability following chemotherapy (20).

However, the biological factors determining the progression of tumours remain to be clarified (4).

OPG may occur anywhere in the course of the visual pathway. Dodge classification, designed in 1958, categorised tumours into three types according to localisation and served as a guide for choosing therapy and selecting patients for resection. The arrival of MRI enabled more precise localisation of OPG according to the modified Dodge classification, shown in fig. 7 (38). The most common functional symptoms of OPG are worse VA and nystagmus (36). Disorders of the visual field and colour perception, and strabismus may also occur. If the patient's life is not threatened, the treatment's goal is to halt VA loss and avoid blindness. These factors are linked with marked deterioration of quality of life. The risk of VA loss is increased if a tumour is bilateral, or if it appears in the chiasmal region (12, 18, 16, 35). In the case of a chiasmal tumour, further propagation into the hypothalamus may occur, thereby afflicting the hypothalamic-pituitary-gonadal axis, causing premature puberty and diencephalic syndrome. OPG occurs in connection with NF1 (NF1+) or sporadically (NF1-). In the literature, the proportion of sporadic OPG is within the range of 30-60% (11, 16, 17, 25, 29, 37). Symptoms appear in 91% of NF1+ patients, whereas in the sporadic type they appear in only 29% of cases (36). Their manifestations are diverse and require individual care.

INCIDENCE

NF1 is the most important risk factor for OPG. In children with NF1, OPG occurs in 15-25% of cases (6, 17), but in one study, the incidence was 76% (12). As a rule it appears in the first decade of life, but approximately 50% of patients are asymptomatic during this period (4, 18). NF1 mutation affects girls more often than boys (17, 36), and OPG occurs more frequently in girls upon diagnosis of NF1 (5). In girls, the occurrence of a tumour is more probable in the post-chiasmal region, but girls show better results of treatment than boys (36). Literature suggests that VA deterioration occurs in 20-70% of patients, despite therapy (5). A risk factor is age under 2 years and over 5 years (17). Both optic nerves are affected in 46% of patients with NF1 and 17% of patients with sporadic OPG. According to

Table 1. Neurofibromatosis type 1 – diagnostic criteria

National Institute of Neurological Disorders and Stroke: Neurofibromatosis Fact Sheet (USA), 2011 (41)

2 or more of the following 7 criteria:	
1	6 or more café-au-lait stains on skin with a diameter of > 5 mm in children and > 15 mm in adults
2	2 or more neurofibromas, or one plexiform neurofibroma
3	Freckling in underarm or groin area
4	2 or more Lisch nodules on iris
5	Abnormal development of spine (scoliosis), sphenoid skull bone or tibia
6	Primary optic pathway glioma
7	Parent, sibling or child with NF1

Source: own illustration

some studies, sporadic OPG is located more frequently in the chiasma (36, 37, 38). If a tumour is present in the post-chiasmatal region, the risk of loss of sight is 2 times higher (5). Moreover, in patients with NF1 and OPG there is a documented risk of secondary tumours following treatment by radiotherapy (37).

Sporadic OPG has a more aggressive character and worse prognosis for the development of VA. Even if at the beginning sporadic OPG has a worse prognosis for survival (37), the results of long-term observation indicate that after 15 years the difference between NF1+ and NF1- patients is erased (34). Nystagmus is a characteristic symptom of the sporadic form of OPG localised in the chiasmatal region and in the hypothalamus (36, 38).

TREATMENT

Patients with OPG have a relatively good prognosis for survival, which nonetheless decreases over from 95% 5 years after diagnosis to 92% after 10 years, 81% after 15 and 76% after 18 years. The length of observation of patients in the literature ranges up to 10 years, and as a result it is possible that it does not fully capture the true nature of this pathology. In addition, the risk of death is 3 times higher in patients diagnosed before the first year of life and as much as 5 times higher upon the occurrence of intracranial hypertension, which offers itself as a prognostic factor of survival (34). Since OPGs in patients with NF1 are generally not aggressive, the purpose of treatment is preservation of VA (16). The choice of treatment is based on the age of the patient, localisation of tumours, and expressed clinical symptoms. In certain cases, resection is selected to reduce the volume of the tumour. Resection is linked with a better prognosis for survival and stabilisation of the tumour but may result in blindness, damage to the hypothalamus, vascular complications, and deterioration of endocrine functions (1, 3). A study of 109 NF1+ patients with OPG points to tumour localisation and surgical procedure as risk factors for the progression of the tumour (12). At the international conference of paediatric neurosurgery in Paris in 2011, it was agreed that a surgical procedure was not the standard primary therapy, even if resection is acceptable in certain cases with lower risks (41). Biopsy is recommended to ensure certainty in diagnosis and is useful if an atypical finding appears on MRI

(1). **Chemotherapy** is currently the standard procedure. In 60–80% of patients, OPG is diagnosed before the age of 5, and chemotherapy is indicated if a deterioration of VA is recorded, or if there is an unacceptable progression of the tumour (5, 9, 11, 25, 29, 34, 36, 37). Asymptomatic progression of the tumour alone is not sufficient for the commencement of treatment, since the OPG may be benign and the correlation between the progression of a tumour and VA is not reliable (5, 9, 11, 25, 28). Risk factors are low age and tumours in the chiasm or hypothalamus, in which a deterioration of VA has been recorded in 32% of cases (11). The best results of VA following chemotherapy are recorded in patients between the age of 2 and 5 (17). However, the effectiveness of chemotherapy on preserving sight has been disputed by numerous studies. The most frequent result of chemotherapy, in approximately 50% of cases, is a stabilisation of VA at its level before the treatment (9, 11, 28). In patients who commenced chemotherapy with baseline VA worse than 6/24, a further deterioration of VA was recorded (25). In one study it is even stated that none of the patients recorded an improvement of VA after chemotherapy (17). The most effective treatment for the preservation of VA appears to be radiotherapy (28). However, this treatment has a range of adverse effects, such as vascular and endocrine dysfunctions, and deterioration of cognitive functions in children younger than 5 years of age (3, 11). In patients younger than 5 years of age, chemotherapy is usually applied to defer **radiotherapy**. However, NF1 syndrome causes learning and behavioural disorders, as well as mild mental retardation (13, 39). As a result, there is a question as to whether the risk of deterioration of cognitive functions in NF1 patients is a sufficient reason for deferring radiotherapy. Further clinical tests are required to confirm this hypothesis (3, 28).

RETROSPECTIVE STUDY

INTRODUCTION

This retrospective study aims to analyse a cohort of patients with OPG and to compare the obtained data with international publications. In the healthcare documentation of the Children's Ophthalmology Clinic and the Children's Oncology Clinic of the Faculty of Medicine at the Masaryk University and University Hospital Brno, 47 children with OPG were identified. All the patients were observed at the Children's Ophthalmology Clinic of the Faculty of Medicine at the Masaryk University and University Hospital Brno during the period from January 2013 to June 2018.

METHOD

The criteria for inclusion in the cohort covered: age at the time of diagnosis, NF1 status, sex, localisation of tumour according to MDC performed by radiologist, and VA before and after treatment. In addition, the documentation had to include a description of the development of the radiological findings and clinical symptoms. VA was evaluated on a Snellen chart, in children of pre-school age pictorial optotypes or Pflüger optotypes were used. In children younger than 3 years of age, preferential vision was examined with the aid of a Cardiff and Single Book test. These criteria were met by 37 patients.

RESULTS

Of the 37 patients with OPG, 15 were girls and 22 boys. Sporadic OPG occurred in 27% of cases (n = 10) and was equally represented in both sexes. The majority of OPGs (73%) were linked with NF1; among girls the incidence of NF1 was in 66% of cases (n = 10), in boys in 77% (n = 17). In the group of NF1+ patients the median age was 2 years and 9 months and in the NF1- group the median was 4 years and 3 months. In both groups the optic nerve was most frequently affected. Sporadic OPG had a higher probability of manifestation in the optic nerve, chiasmal, and post-chiasmal region. In both groups, the number of occurrences of the bilateral tumour was comparable, as shown in graph 1 and table 2.

Nystagmus was a characteristic finding in the NF1- group (n = 3 vs. n = 0 in NF1+). Hydrocephalus appeared in 3 patients, of whom one was from the NF1+ group.

The prognosis for VA in patients with a sporadic tumour is poor. At the last examination, out of 20 eyes (n = 10 patients), there were only 5 eyes with stable VA of 6/6 (25%). One eye recorded VA improvement from 6/24 to 6/6. 13 eyes (65%) were amaurotic, and according to the World Health Organization fell within one of three categories of blindness. One eye had to be enucleated. The course of the pathology and the resulting VA were fundamentally better in the NF1+ patients. Out of 27 NF1+ patients, 59% (n = 17) were merely observed. Out of 34 eyes in this group, 20 eyes were with VA of 6/6 throughout the entire observation period, and 7 eyes spontaneously improved by 1 to 2 rows. Stability of VA was recorded in 7 eyes. The remaining 10 patients (20 eyes) underwent treatment by chemotherapy. Three types of treatment were used: the SIOP protocol (carboplatin and vincristine; 6 patients), the ACNS protocol (carboplatin, vincristine, temozolo-

Graph 1. Distribution of tumours according to modified Dodge classification

mid; 3 patients), and monotherapy with carboplatin (1 patient). The results of treatment in 3 eyes were a deterioration of VA and in one eye an improvement of VA by one row, 80% of eyes recorded stability. Eyes with baseline VA better than 6/24 recorded stabilisation after chemotherapy, while eyes with baseline VA of 6/24 or less recorded a deterioration of VA after treatment.

DISCUSSION

In the group of patients with NF1, in contrast with the literature OPG occurred more frequently in boys (63% vs. 37%). In this group, neither increased incidence of OPG in the chiasm in comparison with other localisations nor more frequent incidence of bilateral OPG in comparison with the NF1- group, was demonstrated (12, 17, 36, 37).

The main problems, which this study also encountered, were low frequency of follow-up eye examinations and variable time interval between them (17, 28). These examinations are important for three reasons.

Firstly, they serve to determine whether a patient undergoing a treatment has a stable VA in the long-term, or if the VA deteriorates over the course of the treatment. In all of the patients in this study, before the commencement of the therapeutic procedure, the results of VA from two or more examinations were available only rarely. As a result, it was not possible to determine whether the deterioration of VA had been taking place at the time of commencement of treatment. In the literature, it is stated that an improvement of sight following treatment is rather the exception (0-32%), which is in congruence with this study (16%) (17, 25). It is necessary to consider whether chemotherapy represents an unnecessary burden on patients with a stable VA. Literature research states that in certain cases it may not be possible to prevent deterioration of VA by means of chemotherapy (9). It is in the general interest to identify these cases and not to commence treatment if the natural development of the pathology would have the same consequence for VA as chemotherapy. Because up-to-day genetic analysis does not enable prediction of the severity of OPG, it is necessary to ensure regular, standardised ophthalmological observation of NF1 patients and patients with diagnosed OPG (5). This study furthermore documents that in the group with NF1, an improvement of VA most often occurred spontaneously (32%). For patients without NF1, these statistics are unavailable because all 10 patients underwent treatment, and only one recorded an improvement of VA (10%). A confirmed characteristic finding in the NF1- group was nystagmus (36). The results further confirm that the sporadic form of OPG has a more rapid and serious course, usually requiring immediate treatment (36, 37).

The second aim of regular eye examinations is to evaluate the influence of the tumour on VA. The poor correlation of the progression of the tumour and VA, which is well documented in the literature, excludes radiological finding as the sole criterion for commencement of treatment, because it cannot counter the accompanying risks (6, 9, 11, 17). Factors considered clinically significant are 1) deterioration of VA by 0.2 or more logMAR (Logarithm of the Minimum Angle of Resolution), 2) confirmation of deteriorating VA or 3) a new finding (10). Due to insufficient data, this correlation was not investigated in this study. Regular eye checks further serve to identify patients with risk factors. The first risk factor is VA worse than 6/24 before the commencement of treatment, because the result is generally a further deterioration (25). The second factor is age of less than 2 years or more than 5 years. In a study of 115 patients there was a deterioration following chemotherapy in 50% of patients younger than 2 years and also in 36% older than 5 years (17). The majority of children with OPG are treated before reaching 1 year of age (10, 35). Baseline VA worse than 6/24 and low age were risk factors also in this cohort of patients. In NF1- patients the median age was 2 years and 9 months,

and median VA 6/24, in the NF1+ patients 4 years and 3 months with VA of 6/6. The results confirmed not only the predictive capability of these factors but also documented the more aggressive course of the sporadic form of OPG. The third risk factor is bilateral affliction or localisation of the tumour in the chiasm/post-chiasmal region or the hypothalamus, which causes long-term deterioration of VA in 32% of patients (11, 36). The influence of localisation of the tumour on the resulting VA, which is currently the subject of examination, could not be evaluated in our study (38). Except for intraconal, chiasmal, and hypothalamic tumours, VA result following the first chemotherapy has a long-term predictive capability. Therefore, it is necessary to carefully consider secondary treatment if the first result is unsatisfactory (11). The third argument for more frequent ophthalmological examination is to evaluate the treatment and long-term prognosis, which although worse in the short term for the NF1- group, may be the same as in the NF1+ group in the long term (34). Frequent problems, to which attention has been drawn also by other authors of retrospective studies, are non-standard and insufficient evaluation of VA. In a number of patients treated with chemotherapy, who were transferred into our care from other centers, the baseline value of VA was not recorded, and it was therefore not possible to confirm the effectiveness of treatment. In this case, it is important to ensure the co-operation of the patient with the doctor and respect the appointments for follow-up examinations. If it is not possible to evaluate VA objectively due to lack of co-operation on the part of the patient, the VA examination must be repeated within 2 weeks, and if the examination fails to produce results a second time, it is necessary to document this (16). Neither cohort in this study was observed for a sufficiently long period to allow for an objective evaluation of the effectiveness of treatment and a comparison of the long-term survival prognosis between the NF1- and NF1+ groups. Because the chiasmal and post-chiasmal regions are linked with a worse prognosis, it is important to differentiate individual localisations according to the modified Dodge classification. However, some studies do not use this classification, and differences in interpretation exist among individual radiologists. The poor correlation between the tumour volume and its influence on VA may be caused by imprecision in the estimation of the size of the tumour from 2D MRI images. **Volumetric Magnetic Imaging (VMI)** is an alternative method for objective evaluation, but is limited by problems with measuring tumours in the post-chiasmal region (10). Since neither genetic analysis nor biomarkers can reliably predict the development of OPG, it is necessary to ensure regular standardised observation. An annual ophthalmological examination is recommended for children with NF1 (4). This should be performed every 3 months if OPG is confirmed on MRI (5, 15), as shown in table 3.

At each examination, it is necessary to quantitatively evaluate VA and the papilla of the optic nerve on the ocular fundus (16, 35). In small children, VA is evaluated with Teller Cards (Cardiff Test, Single Book), in older children with HOTV

Table 3. Recommended observation intervals for patients with NF1. Source: de Blank P.M.K. et al., 2017 (10)

	Frequency	Period
From diagnosis of NF1 or upon suspicion thereof		
Ophthalmological examination	Every 6 months	Up to 8 years of age
	Every year	Up to 18 years of age
From diagnosis of NF1 and confirmed OPG on MRI		
Ophthalmological examination	Every 3 months	Over a period of 1 year
	Every 6 months	Over a period of 2 years
	subsequently	
	If < 8 years	Every 6 months
	If > 8 years	Every year
		Up to 8 years of age
		Up to 18 years of age
MRI examination		
	Every 3 months	Over a period of 1 year
	Every 6 months	Over a period of 2 years
	Every year	Over a period of 5 years
	Then according to doctor	

optotypes. Examination of VA and the visual field should be conducted at every visit to an ophthalmologist. However, in the case of perimetric examination, necessary patient co-operation is limited by age and the length of examination (5-7 minutes per one eye), and complicated by the increased incidence of attention disorders in patients with NF1 (13, 35, 39). If nystagmus, strabismus, loss of colour perception, edema of the optic nerve, or discolouration of the papilla is recorded, the patient should be monitored with increased attention, similarly as in the case of asymptomatic tumour growth (10). More examinations for statistical purposes are not recommended, although other methods exist which have the potential to serve as a biomarker of VA. **Optical coherence tomography (OCT)**, measuring the thickness of the retinal nerve fiber layer (RNFL), shows promising results. However, the use of OCT as a biomarker of VA is not recommended until a correlation has been demonstrated between RNFL reduction and future VA loss. Although loss of VA often correlates with a reduction of the RNFL, it appears that shrinkage of the RNFL occurs over the long term, and in certain cases continues also after the stabilisation of visual acuity (10). **Visual evoked potentials (VEP)** have high sensitivity (90-100%), and thus may be used for timely identification of a tumour. At the same time, however, they have low specificity (60-69%) and correlate with visual acuity in only 50% of cases (10, 16). Some patients with NF1 show abnormal results even without

OPG (24). Furthermore, VEPs are not able to determine which OPG requires treatment or monitor change of VA related to treatment. As a result they cannot serve as a clinical biomarker, because they cannot identify or predict VA loss before the commencement of the therapeutic procedure (10, 16).

CONCLUSION

At present, the standard treatment of OPG chemotherapy, which is indicated based on the clinical and radiological progression of the tumour. However, the influence of chemotherapy on VA is debatable, since its most frequent result is a stabilisation of VA, and in certain cases is probably impossible to avoid VA loss. For these patients, chemotherapy may represent an unnecessary burden. Unfortunately, no clinical biomarker exists which could reliably predict subsequent loss of VA. Future studies will need to compare the results of radiological findings and ophthalmological examinations with potential clinical biomarkers of VA, observe changes thereof within the same time intervals, and their relationship to treatment. It is also necessary to ensure long-term observation of patients, in order to differentiate short-term improvement from a long-term trend of pathology development. However, this shall be possible only through co-ordination of examinations among individual specialists.
